**ABSTRACT**

**Background:** Limited retrospective data suggest that dipeptidyl peptidase-4 (DPP-4) inhibitors such as sitagliptin may decrease mortality in patients with type 2 diabetes hospitalized with coronavirus disease 2019 (COVID-19).

**Objective:** To review the strength of evidence that supports possible therapeutic role of DPP-4 inhibitors in COVID-19.

**Methods:** PUBMED search until October 10, 2020. Search terms included COVID-19, DPP-4 inhibitors, sitagliptin, CD26, mortality, diabetes. Retrospective studies, pertinent animal investigations and pre-print studies are reviewed.

**Results:** Three retrospective studies have shown that use of DPP-4 inhibitors was associated with significant mortality reduction of approximately 56-87% in patients with diabetes admitted with COVID-19. In addition, in one of these studies, the use of sitagliptin before hospitalization was associated with greater number of hospital discharges, improvement of clinical status, reduced risk of transfer to intensive care unit (ICU) and need for mechanical ventilation compared with patients who were not receiving sitagliptin. Moreover, there was significant decrease in some pro-inflammatory markers in the sitagliptin group. A small retrospective study of 9 patients who were taking a DPP-4 inhibitor prior to admission did not find any significant effect of DPP-4 inhibitors on mortality and clinical outcomes after hospitalization. Results of another small study suggested increase susceptibility to COVID-19, but not to its severity, in patients taking DPP-4 inhibitors.

**Conclusion:** Weak evidence derived from observational studies suggests possible beneficial effects of DPP-4 inhibitors use in patients with type 2 diabetes and COVID-19. Randomized trials are urgently needed to clarify the efficacy and safety of DPP-4 inhibitors in patients with COVID-19 with and without type 2 diabetes.

**Introduction**

Dipeptidyl peptidase-4 (DPP-4) inhibitors such as sitagliptin are oral anti-diabetic agents approved by the Federal Drug Administration (FDA) for treatment of type 2 diabetes. DPP-4, also called CD26, is the enzyme causing breakdown of the incretin hormones glucagon-like peptide-1 (GLP-1) and gastric inhibitory polypeptide (GIP). These 2 incretins normally lower blood glucose levels after meals by stimulation of insulin secretion, inhibition of glucagon production, slowing of gastric emptying, and promotion of early satiety. It follows that inhibition of DPP-4 by DPP-4 inhibitors decreases breakdown of these 2 incretins and prolongs the duration of their anti-hyperglycemic actions [1,2]. Many authors believe that DPP-4 inhibitors could be useful therapeutic agents in patients with COVID-19 with and without type 2 diabetes [3-5]. The purpose of this manuscript is to review available studies related to the relationship between DPP-4 inhibitors and COVID-19.

**Effect of DPP-4 Inhibitors on Mortality in COVID-19**

To the best of authors’ knowledge, only 4 observational studies examined the effects of pre-admission administration of DPP-4 inhibitors on mortality and clinical outcomes in patients with type 2 diabetes and COVID-19. In addition, one study addressed the relationship of use of DPP-4 inhibitors with development of COVID-19 [6,10]. Overview and main findings of these studies are summarized in table 1. The first study conducted by Solerte et al specifically evaluated the effects of sitagliptin on mortality, as primary outcome. This investigation included 338 consecutive patients of whom 169 subjects were taking sitagliptin as part of their anti-diabetic therapy (sitagliptin group) and an equal group of 169 subjects were receiving other diabetes therapy (the control group) [6]. After admission, all oral anti-diabetic agents, including sitagliptin, were discontinued and patients were switched to insulin therapy as per recommendations of American Diabetes Association (ADA) [11]. The use of sitagliptin at the time of hospitalization was associated with significant reduction in mortality; 18% and 37% in the sitagliptin group and control group, respectively (P=0.0001). Thus, after adjustment for clinically relevant factors (age, sex, comorbidities, and ongoing treatments), pre-admission treatment with sitagliptin was associated with a decreased odds-ratio (OR) for in-hospital death; OR 0.44 (95% CI, 0.29-0.66; P=0.0001). The beneficial effect of pre-admission sitagliptin therapy did not
COVID-19 is a non-randomized retrospective design. The latter study groups at baseline in many confounding factors that may affect outcomes. For instance, in the study of Solerte et al, glycemic control was significantly better in the sitagliptin group than in the control group during hospitalization, as well as at follow-up at day 30, with means blood glucose concentrations at 30 days: 139 and 170 mg/dl, respectively [6]. Since poor glycemic control during hospital stay was shown to be independently associated with poor prognosis in COVID-19 patients, this difference in blood glucose values might partly explain the favorable prognosis observed in the sitagliptin group [12].

Mechanisms of the possible protective effects of DPP-4 inhibitors in COVID-19

The rationale of using DPP-4 inhibitors as treatment for COVID-19 is based on 2 hypotheses. First, COVID-19 is caused by a coronavirus called severe acute respiratory syndrome coronavirus 2 (SARS-Cov-2) that uses the angiotensin converting enzyme 2 (ACE2) as receptor and the transmembrane protease serine 2 (TMPRSS2) as co-receptor for host cell binding and penetration. However, Vankadari and Wilce have shown that CD26 could be also involved in binding of SARS-Cov-2 to its target cells. Therefore, inhibition of CD26 by DPP-4 inhibitors could virtually inhibit viral penetration into host cells. Second, both animal and human studies have shown that sitagliptin might exert anti-inflammatory actions. Thus, sitagliptin administration results in inhibition of pro-inflammatory cytokines such as tumor necrosis factor-α (TNF-α) and CRP [14–16]. Accordingly, sitagliptin could virtually inhibit the severe inflammatory reaction and cytokine storm that occur in COVID-19 and represent a major cause of death. This hypothesis is in agreement with the findings Solerte et al [6] who observed that patients who were receiving sitagliptin prior to admission had significant reduction in serum markers of inflammation such as CRP and procalcitonin. In addition, in patients with type 2 diabetes, Satoh-Asahara et al [15] have shown that sitagliptin therapy was associated with significant increase in expression of the anti-inflammatory cytokine interleukin-10 (IL-10), a finding that further supports the inflammation-suppressive effects of sitagliptin.

Metformin and COVID-19 Related Mortality

Multiple retrospective studies have shown significant mortality reduction in patients admitted with COVID-19 who were taking metformin, possibly due to its anti-inflammatory effects. The most comprehensive data in this respect was derived from the recent meta-analysis conducted by Kow and Hassan [18]. In the latter study, the authors analyzed data (up to August 8, 2020) of 5 studies including 8,121 patients with diabetes and COVID-19 who were using metformin prior to hospital admission. Pooled analysis revealed a significantly reduced risk for mortality with the use of metformin prior to admission, pooled odds ratio (OR) being 0.62 (95% CI, 0.43-0.89) compared to patients with diabetes who were not using metformin [17,18]. Interestingly, this mortality benefit of metformin was not demonstrated in the studies of DPP-4 inhibitors mentioned above. Thus, in the study of Solerte et al [6], pre-admission therapy with metformin did not have any effects on clinical outcomes. Meanwhile, in the study of Mirani et al [7], there was a trend towards mortality reduction among COVID-19 patients who were taking metformin prior to hospitalization. Yet, this trend did not reach statistical significance; adjusted OR 0.55, 95% CI (0.27-1.11). Nevertheless, further data are needed as studies of both DPP-4 inhibitors and metformin suffer from similar limitations with respect to their non-randomized designs.
Conclusions and Current Directions

It is tempting to speculate that DPP-4 inhibitors such as sitagliptin may have protective effects in COVID-19. This concept is based on results of 3 retrospective investigations showing substantial reduction in mortality in patients with COVID-19 and type 2 diabetes taking DPP-4 inhibitors prior to hospitalization. The decrease in mortality was associated with significant improvement of clinical status and decrease in need for ICU transfer and mechanical ventilation. Moreover, in one study, the DPP-4 inhibitor was continued during hospitalization. Indeed, the latter study reported the highest reduction in mortality in association with the use of in-hospital DPP-4 inhibitors, approximately 87% reduction (table 1). However, another retrospective study failed to demonstrate such benefits in a limited number of 9 patients [6-9]. Nevertheless, there are plausible mechanisms whereby DPP-4 inhibitors could be useful agents for treatment of COVID-19 including their anti-inflammatory actions, and possibly interference with SARS-Cov-2 penetration into host cells through CD26 inhibition. Randomized trials are urgently needed to clarify the therapeutic role of DPP-4 inhibitors in hospitalized patients with COVID-19. It is worthwhile to evaluate patients with and without type 2 diabetes in these trials to see to what extent the beneficial actions of DPP-4 inhibitors are related to their anti-diabetic effects.
